Some aspects of extracting the information on the structure of virtual photons from jet production in ep and e^+e^- collisions are discussed.

1 Virtual particles - why, where and how?

Measuring the dependence of the structure of the photon at short distance on its virtuality provides new information on strong interaction dynamics. The results of first attempts in this direction have recently been reported¹. Presently the structure of virtual photons can be investigated via the deep inelastic scattering or jet production in $\gamma\gamma$ collisions at LEP, or in jet production in γp collisions at HERA. In jet studies the internal structure of the photon manifests itself through the resolved photon contribution to hard γp or $\gamma\gamma$ collisions. Measuring the deviation of jet cross-sections from expectations of a structureless photon provides information on the distribution functions $f_{i/\gamma}(x, M^2, P^2)$ of partons inside the photon of virtuality P^2 , probed at the distance $1/M$. In Fig. 1a we compare the integrated cross-sections for the DIS and dijet production

$$\sigma^{\text{DIS}}(M^2) \equiv \int_{M^2} dQ^2 \int dx \frac{d\sigma(x, Q^2)}{dx dQ^2}, \quad \sigma^{\text{jets}}(M^2) \equiv \int_M dp_T \int d\eta \frac{d\sigma(\eta, p_T)}{d\eta dp_T}$$

in e^+e^- collisions at LEP 2 for photons with $P^2 < 1 \text{ GeV}^2$. The hard scale is identified with the standard Q in DIS and p_T in jet production. The curves in Fig. 1a show that up to moderate scales jet production is more effective than DIS, while for M^2 above 40 GeV^2 DIS has larger cross-section. Although both cross-sections decrease with increasing P^2 , their ratio is essentially independent of it. To obtain reasonable statistics of a few thousands of events it will be necessary to use jets with transverse momenta down to 3-4 GeV. In ² we discussed the possibilities offered by the HERA upgrade for the measurement of basic features of the virtual photon structure via the jet production. Here we elaborate on two important aspects of this problem.

^aTalk presented at PHOTON '97 Conference in Egmond aan Zee

Figure 1: Integrated cross-sections of γ with $Q^2 \leq 1 \text{ GeV}^2$ for the DIS and jet production in e^+e^- collisions at LEP 2, using the GRV structure functions for the photon and disregarding any detector efficiencies (a), kinematical ranges of the pseudorapidity of jets (solid lines) and beam remnants at HERA (dashed) (b). In (b) the thick solid and dashed lines indicate the centers of the respective intervals and the dotted one the end of the H1 detector.

2 WW approximation and the structure of the virtual photon

The measured electroproduction cross-sections at the CMS energy $\sqrt{S}$ are related to those of the photoproduction via the WW approximation as

$$d\sigma(e + p \rightarrow e' + X; S) = \int \int dy dP^2 f_{\gamma/e}(y, P^2) d\sigma(\gamma + p \rightarrow X; yS, P^2),$$

where $f_{\gamma/e}(y, P^2)$ is the unintegrated distribution function of virtual photons inside an electron. This relation holds for P^2 much smaller than the scale of the $\gamma + p \rightarrow X$ process. If this latter process is characterized by the hard scale Q , its cross-section can in turn be expressed in terms of the convolution of integrated parton distribution functions (pdf) $f_{i/\gamma}(x_\gamma, Q^2, P^2)$ of the photon with those of the proton, $f_{j/p}(x_p, Q^2)$, and partonic hard scattering cross-section σ_{ij} . Because virtual photons can be transverse as well as longitudinal, there are two independent fluxes. Neglecting subdominant terms we have

$$\begin{aligned} f_{\gamma/e}^T(x, P^2) &= \frac{\alpha}{2\pi} \frac{1 + (1-x)^2}{x} \frac{1}{P^2} \equiv \frac{F^T(x)}{P^2}, \\ f_{\gamma/e}^L(x, P^2) &= \frac{\alpha}{2\pi} \frac{2(1-x)}{x} \frac{1}{P^2} \equiv \frac{F^L(x)}{P^2}. \end{aligned}$$

As $P^2 \rightarrow 0$, $f_{i/\gamma}^{T,L}$ behave as

$$f_{i/\gamma}^T(x, Q^2, P^2) = f_{i/\gamma}^{\text{real}}(x, Q^2) + (P^2/\mu_T^2) h_i^T(x, Q^2) + O(P^4),$$

$$f_{i/\gamma}^L(x, Q^2, P^2) = (P^2/\mu_L^2)h_i^L(x, Q^2) + O(P^4),$$

where $\mu_{T,L}$ are some parameters. In most of existing phenomenological analyses^b of the photon structure its longitudinal component f^L has been neglected. This is, however, consistent only if we at the same time neglect also the dependence of $f_{i/\gamma}^T(x, Q^2, P^2)$ on the virtuality P^2 ! Indeed, as

$$\begin{aligned} f_{\gamma/e}^T(P^2) \otimes f_{i/\gamma}^T(Q^2, P^2) &= (1/P^2)F^T \otimes f_{i/\gamma}^{\text{real}}(Q^2) + (1/\mu_T^2)F^T \otimes h_i^T(Q^2), \\ f_{\gamma/e}^L(P^2) \otimes f_{i/\gamma}^L(Q^2, P^2) &= (1/\mu_L^2)F^L \otimes h_i^L(Q^2), \end{aligned}$$

$f_{\gamma/e}^L$ contributes terms of the same order as the subleading, $O(P^2)$, term in $f_{\gamma/e}^T$! Thus to investigate P^2 dependence of photon structure, we must take into account also its longitudinal component. Details will be discussed in⁸. The P^2 dependence of the photon pdf has recently been addressed in a number of papers^{4,5,6,7}. For instance, in⁵ the virtuality dependence of $f_{\gamma/e}^T$ is assumed to be given by a simple multiplicative suppression factor L

$$f_{q/\gamma}^T(x, Q^2, P^2) = L(Q^2, P^2, P_c^2)f_{q/\gamma}^{\text{real}}(x, Q^2), \quad L \equiv \frac{\ln((Q^2 + P_c^2)/(P^2 + P_c^2))}{\ln((Q^2 + P_c^2)/P_c^2)}.$$

As for $P^2 \rightarrow 0$, $L \approx 1 - (P^2/P_c^2)/\ln(Q^2/P_c^2)$, the parameter P_c plays the role of μ_T . For the gluon the suppression factor is taken as L^2 . This simple ansatz, incorporated in HERWIG event generator, was used in².

3 Jets vs. the underlying event in ep collisions at HERA

Also at HERA the studies of resolved photon processes with P^2 above, say, 0.5 GeV², will require using jets with E_T down to about 5 GeV². The properties of such low E_T jets can, however, be significantly distorted by the presence of soft particles produced in the *soft underlying event* (sue), which appears, in one form or another, in all event generators. For instance, the H1 found⁹ significant disagreement between their data on jets with $E_T^{\text{jet}} \approx 7$ GeV and PYTHIA and HERWIG event generators without the sue. For PYTHIA this discrepancy disappeared when the multiple interaction option with a very small partonic $p_T^{\text{min}} = 1.2$ GeV was used. The presence of sue may also be the cause of the discrepancy between NLO calculations of dijet cross-sections in photoproduction and ZEUS data^{10,11} in the region $x_\gamma \leq 0.75$, $E_T^{\text{jet}} \leq 10$ GeV.

In HERWIG the sue is modelled as the soft interaction of two beam remnant clusters, which accompanies the basic hard parton-parton scattering. The

^bThe relevance of the longitudinal part $f_{\gamma/e}^L$ has recently been discussed in³.

main effect of this soft collision is the redistribution of the (usually large) longitudinal energy of the two beam remnant clusters. Without sue these remnant clusters decay into just a few particles, separated by a large rapidity gap. In a sue event this longitudinal energy is redistributed among many softer particles which populate central region in pseudorapidity and thus provide “pedestal” under the jets. The strength and frequency of the sue is governed by two parameters, which can be tuned to data. As there are so far no conclusive results on the magnitude of sue needed by the data we performed our studies for two extreme options: no sue and sue in each event and with all the energy of beam remnants used up for the soft collision. The differences between these two scenarios, shown in Figs. 2,3, illustrate the importance of a good quantitative understanding of nonjet physics for the determination of jet properties.

We defined jets using the CDF cone algorithm with $R = 1$ and required $E_T \geq 5$ GeV in γp CMS. The crucial question is how much transverse energy of the sue populates the region in η where jets are found. For a given $x_\gamma \equiv (E_T^{(1)} \exp(-\eta_1) + E_T^{(2)} \exp(-\eta_2))/2E_\gamma$, x_p , W and p_T^{jet} simple kinematics allows us to determine the intervals of η^{jet} and η^{remn} , populated by jets and by soft particles from beam remnant fragmentation respectively. In Fig. 1b they correspond, as a function of a x_γ and for fixed typical $x_p = 0.05$, $p_T^{\text{jet}} = 5$ GeV and two values of $W = 75, 200$ GeV, to intervals on the y axis between the solid (for jets) and dashed curves (for beam remnants). We see that except for x_γ very close to 1, jets can bath in a pool of soft particles from beam fragmentation. Whether they indeed do so depends on the way beam remnants fragment. In Fig. 2 we show, for events with and without sue, normalized lego-plots of E_T as a function of η^{jet} and x_γ for jets and η^{remn} and x_γ for particles from beam remnants. Without the sue jets and beam remnants overlap significantly only for large x_γ , while for events with the sue they do so for all values of x_γ . Moreover, the amount of transverse energy under the jets coming from beam remnant fragmentation is almost negligible for events without the sue, but becomes quite sizeable for the sue option. There is always some transverse energy under the jets which distorts its properties, but above certain value it makes the theoretical predictions unstable and thus unreliable. Too much transverse energy from sue leads to fake hard jets, which significantly increase the corresponding cross-section. We studied this effect in HERWIG by generating events with p_T^{part} of the basic partonic subprocess starting from 2 GeV and looked for jets with E_T between 5 and 12 GeV. The results, plotted in Fig. 3a, show that without the sue (dashed curves), the contributions to jets with a given E_T^{jet} come mainly from partons with $p_T^{\text{part}} \doteq E_T^{\text{jet}} + 1$ and drop off rapidly below and more slowly above E_T^{jet} . Summing the contributions of all events with $p_T^{\text{part}} > 2$ GeV yields the dashed curves in Fig. 3b. The jet cross-sections

Figure 2: Transverse energy flow per event as a function of x_γ and pseudorapidity of jets or particles from beam remnants in events with (a,b) and without (c,d) the sue.

are reasonably stable with respect to the variation of the minimal partonic $p_T^{\min}$ down to $E_T^{\text{jet}} = 5$ GeV. For events with sue the situation, described by solid curves in Fig. 3, is substantially different. Even events with $p_T = 2$ GeV can fake jets with E_T^{jet} below 10 GeV and this probability in fact increases with decreasing p_T^{part} ! A closer scrutiny shows that these fake hard jets are characterized by almost no correlation between the momenta of basic hard parton scattering process and the observed jets. Only for E_T^{jet} above roughly 10 GeV we get the situation analogous to that of dashed curves. The integrated jet cross-sections in Fig. 3b are then highly unstable with respect to the minimal partonic $p_T^{\min}$, which makes the theoretical predictions unreliable. In order to make sensible comparisons between theory and data the amount of transverse energy under the jets (jet pedestals) must be determined experimentally and subtracted from measured jets transverse energy. This is in particular true for comparisons at the NLO, where theoretical calculations are available on

Figure 3: The contribution of a given events with given p_T^{part} to the cross-section for production of jets with E_T^{jet} between 5 and 12 GeV (a) and sums of these contribution above a given minimal partonic $p_T^{\min}$ (b).

partonic level only. Comparing theoretical prediction directly with observed jets makes sense only if the theory describes quantitatively also the transverse energy flow outside the jets. This point will be discussed in more detail in ⁸.
